CS33 Intro to Computer Systems

## **Processor: Basic Operation**

```
while (forever) {
  fetch instruction IP points at
  decode instruction
  fetch operands
  execute
  store results
  update IP and condition code
}
```

IX-5

# Instructions ...

Op code | Operand1 | Operand2 | ...

CS33 Intro to Computer Systems

IX-6

# **Operands**

- Form
  - immediate vs. reference
    - » value vs. address
- How many?

```
- 3

» add a,b,c

• c = a + b

- 2

» add a,b

• b += a
```

CS33 Intro to Computer Systems

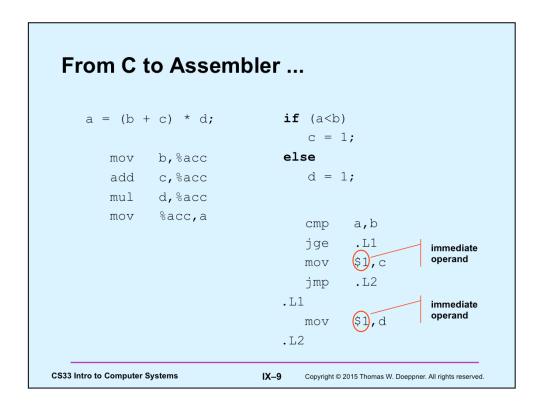

IX-7

## **Operands** (continued)

- Accumulator
  - special memory in the processor
    - » known as a register
    - » fast access
  - allows single-operand instructions
    - » add a
      - acc += a
    - » add b
      - acc += b

CS33 Intro to Computer Systems

IX-8

Note we're using the accumulator in two-operand instructions. The "%" makes it clear that "acc" is a register. The "\$" indicates that what follows is an immediate operand; i.e., it's a value to be used as is, rather than an address or a register.

### **Condition Codes**

- Set of flags including status of most recent operation:
  - zero flag
    - » result was or was not zero
  - sign flag
    - » result was or was not negative (sign bit is or is not set)
  - overflow flag
    - » for values treated as signed
  - carry flag
    - » for values treated as unsigned
- Set implicitly by arithmetic instructions
- · Set explicitly by compare instruction
  - cmp a,b
    - » sets flags based on result of b-a

**CS33 Intro to Computer Systems** 

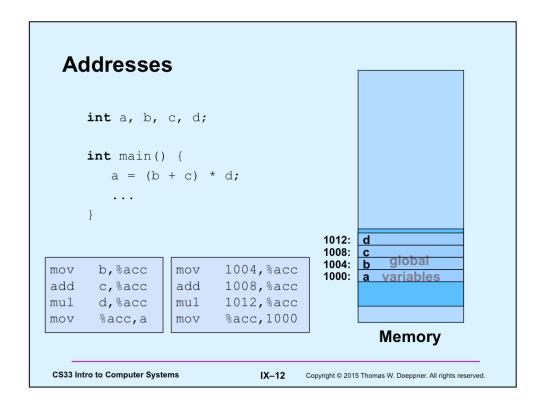

IX-10

## **Jump Instructions**

- Unconditional jump
  - just do it
- Conditional jump
  - to jump or not to jump determined by conditioncode flags
  - field in the op code indicates how this is computed
  - in assembler language, simply say
    - » je
      - · jump on equal
    - » jne
      - jump on not equal
    - » jgt
      - jump on greater than
    - » etc.

IX-11

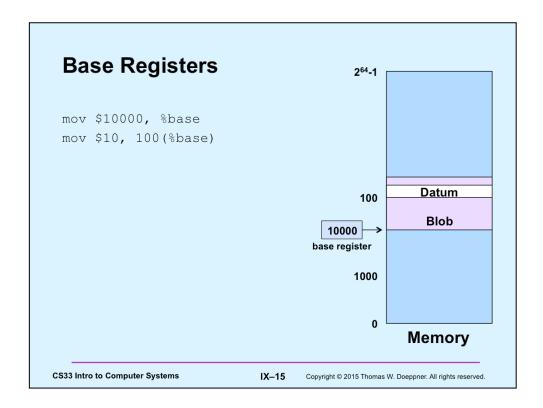

In the C code above, the assignment to a might be coded in assembler as shown in the box in the lower left. But this brings up the question, where are the values represented by a, b, c, and d? Variable names are part of the C language, not assembler. Let's assume that these global variables are located at addresses 1000, 1004, 1008, and 1012, as shown on the right. Thus correct assembler language would be as in the middle box, which deals with addresses, not variable names. Note that "mov 1004, "acc" means to copy the contents of location 1004 to the accumulator register; it does not mean to copy the integer 1004 into the register!

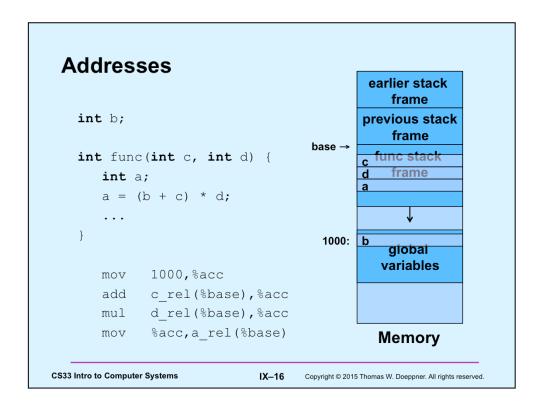

```
Addresses
     int b;
     int func(int c, int d) {
         int a;
         a = (b + c) * d;
                                    One copy of b for duration of
                                    program's execution
      }
                                     • b's address is the same
                                         for each call to func
                 ?, %acc
         mov
                                    Different copies of a, c, and d
         add
                  ?,%acc
                                    for each call to func
                                     · addresses are different in
                  ?,%acc
         mul
                                         each call
                  %acc,?
         mov

```

Here we rearrange things a bit. b is a global variable, but a is a local variable within func, and c and d are arguments. The issue here is that the locations associated with a, c, and d will, in general, be different for each call to func. Thus we somehow must modify the assembler code to take this into account.

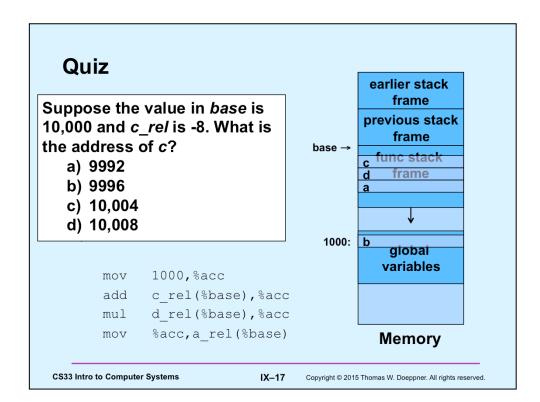

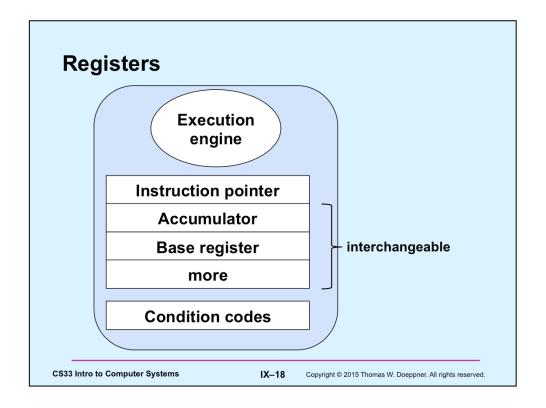

Here we load the value 10,000 into the base register (recall that the "\$" means what follows is a literal value; a "%" sign means that what follows is the name of a register), then store the value 10 into the memory location 10100 (the contents of the base register plus 100): the notation n(%base) means the address obtained by adding n to the contents of the base register.

Here we return to our earlier example. We assume that, as part of the call to func, the base register is loaded with the address of the beginning of func's current stack frame, and that the local variable a and the parameters c and d are located within the frame. Thus we refer to them by their offset from the beginning of the stack frame, which are assumed to be  $a\_rel$ ,  $c\_rel$ , and  $d\_rel$ . Note that since the stack grows from higher addresses to lower addresses, these offsets are negative. Note that the first assembler instruction copies the contents of location 1000 into %acc.

We've now seen four registers: the instruction pointer, the accumulator, the base register, and the condition codes. The accumulator is used to hold intermediate results for arithmetic; the base register is used to hold addresses for relative addressing. There's no particular reason why the accumulator can't be used as the base register and vice versa: thus they may be used interchangeably. Furthermore, it is useful to have more than two such dual-purpose registers. As we will see, the x86 architecture has eight such registers; the x86-64 architecture has 16.
